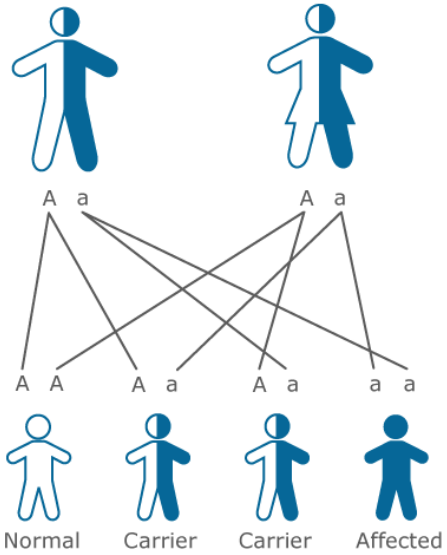
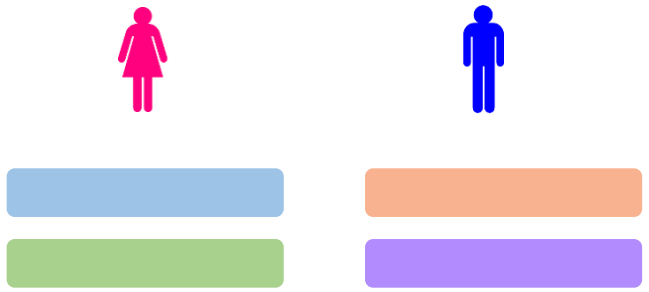
Genetic screening of embryos

- Why?
  - Mendelian disease mutations
  - Recurrent pregnancy loss
- How?
  - Grow IVF embryos for 3-5 days
  - Amplify DNA from a single cell
- What?
  - Traditionally: single mutations, aneuploidy
  - Now: whole-genome haplotypes, CNVs
  - Universal, fast, accurate, low cost



How could it be possible?

Parents (microarray)



- Embryos are a mosaic of the parents
- Only need to infer crossover locations
- (Up to *de-novo* mutations)

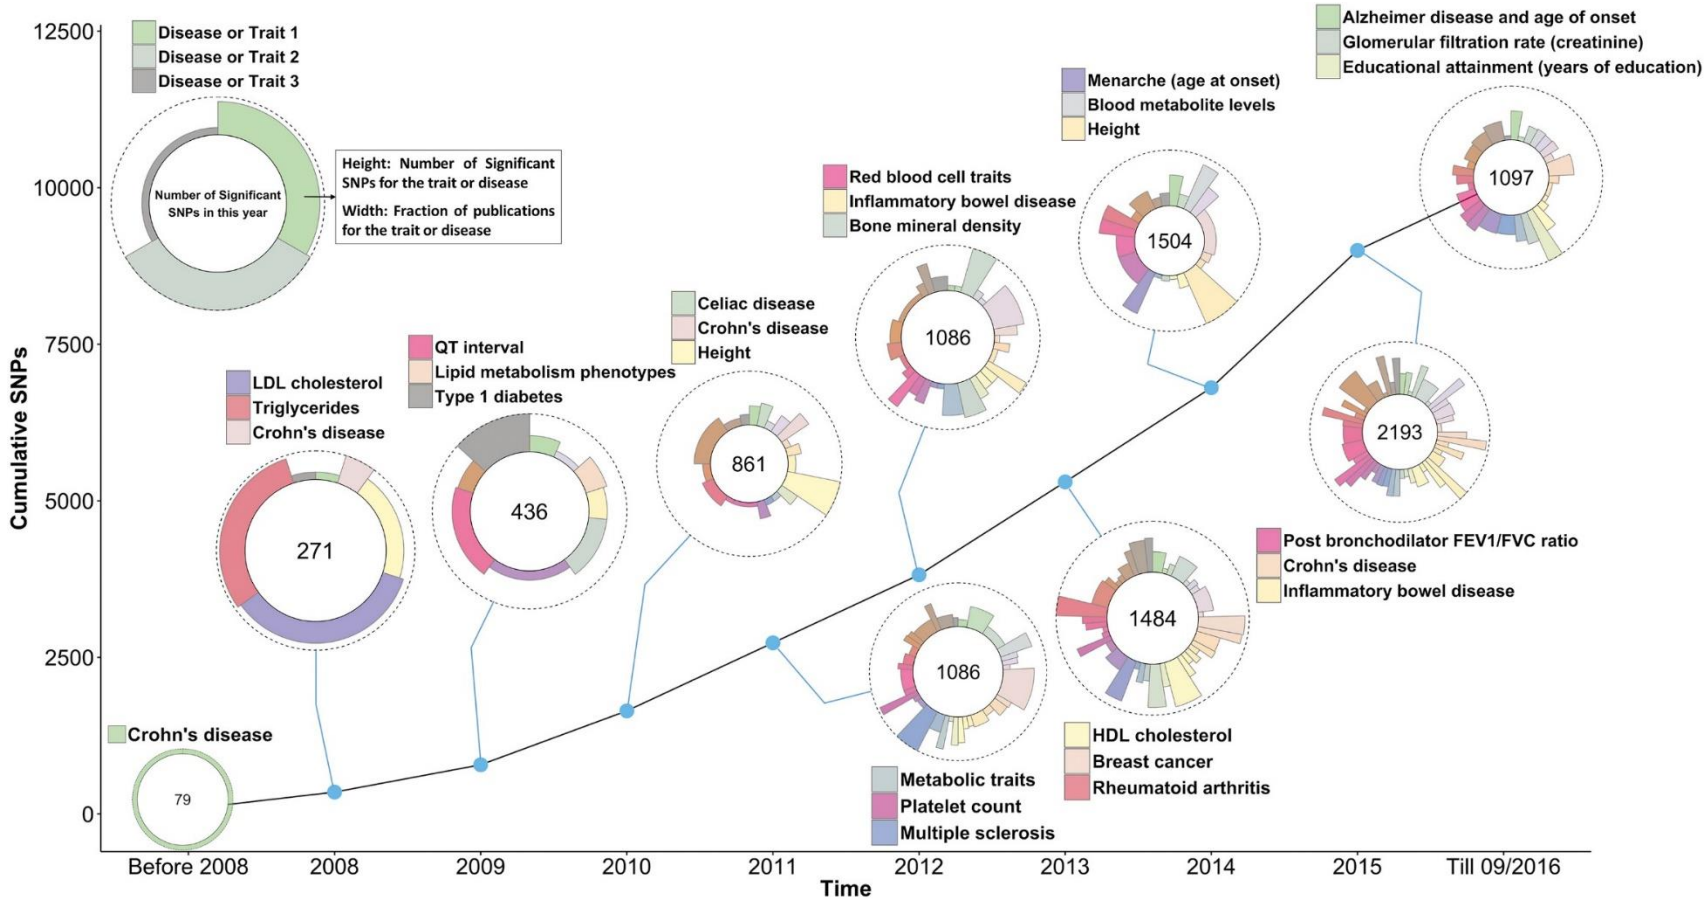
Embryo 1

Embryo 2

Embryo 3

Array/low-coverage sequencing

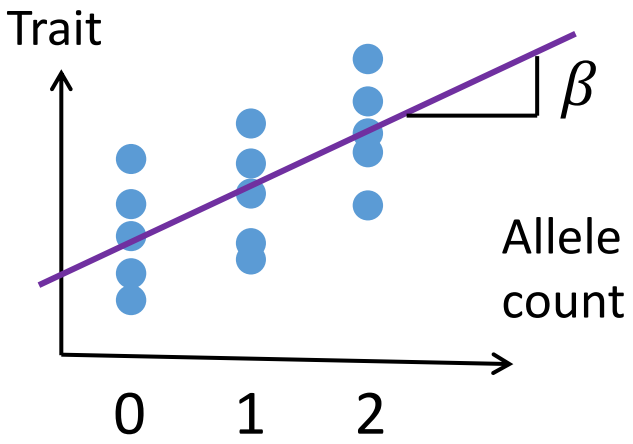
In parallel, progress in complex trait genetics



Visscher et al., 10 Years of GWAS Discovery: Biology, Function, and Translation, AJHG, 2017

Discovery ➔ prediction

- Summary statistics are publicly/freely available



- Effect size:
- Quantitative traits: increase in trait with each allele (regression slope)
- Disease (binary) traits: log odds-ratio

SNP	Chr	Position	Effect allele	P-value	Effect size $\hat{\beta}$
rs1234	1	134346223	A	$2 \cdot 10^{-5}$	0.001
rs2345	3	124572521	G	$4 \cdot 10^{-3}$	-0.0006
rs3456	6	73422152	A	$2 \cdot 10^{-8}$	0.02
rs4567	14	66452342	C	$7 \cdot 10^{-4}$	-0.003

Polygenic scores (PS)

- Using summary statistics, we can predict the trait of a new individual

- $PS = \sum_{i=1}^{M} \hat{\beta}_i g_i$

- M: number of SNPs
- g_i: number of effect alleles at SNP i (0,1,2)
- $\hat{\beta}_i$: estimated effect size at SNP i

- Statistical methods refine the set of SNPs and the weights

Performance of polygenic scores

- h^2: proportion of variance explained by genetics (heritability)
- h^2_{snp}: proportion of variance explained by chip SNPs (SNP heritability)
- r^2_{ps}: proportion of variance explained by score

$$r^2_{ps} < h^2_{snp} < h^2 < 1$$

Trait	h^2	h^2_{snp}	r^2_{ps}	References (PMID)
Height	70-80%	46%	25%	19818695,30124842
BMI	40-70%	25%	10%	22645519, 30124842
Educational attainment	63%	22%	12%	25985137, 23722424, 30038396
Cognitive function	50%	20%	5%	25985137, 29942086
LDL cholesterol	40-50%	13%	3.1-4.7%	17903299, 23766260, 30127800
Blood pressure	47%	14%	4%	25985137, 30224653

Implications

- Screening embryos for complex traits now feasible

- At least one company is already offering the test

Screening embryos for complex traits now feasible

- From GP website:
  - Type 1 and Type 2 Diabetes
  - Coronary Artery Disease, Heart Attack Risk, Hypercholesterolemia, Hypertension
  - Breast Cancer, Testicular Cancer, Prostate Cancer, Malignant Melanoma, Basal Cell Carcinoma
  - Intellectual Disability
  - Idiopathic Short Stature

PROCREATIVE BENEFICENCE: WHY WE SHOULD SELECT THE BEST CHILDREN

JULIAN SAVULESCU

No data!

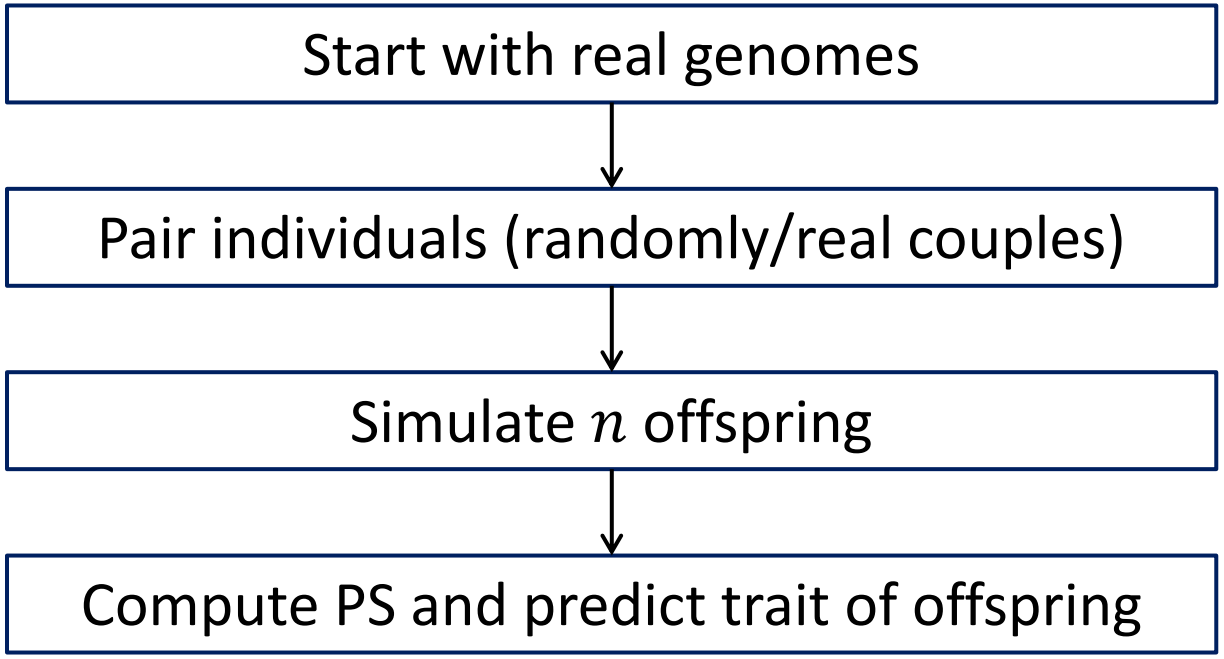
Does it work? What are the expected outcomes?

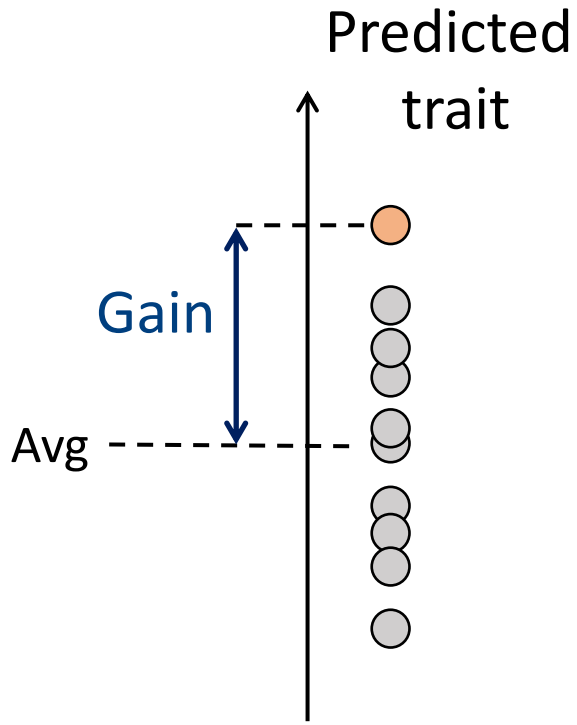
So far: economic analysis, no empirical data (Shulman and Bostrom, 2014; gwern blog)

Our approach:

1. Simulations based on real data
2. Quantitative genetic model
3. Large nuclear families

Simulations overview





Gain = (prediction of top-scoring embryo) — (average prediction)

Traits/cohorts

Gil Atzmon, Nir Barzilai
Einstein College of Medicine

- **Height**
- 102 couples, 700k SNPs
- Ashkenazi Jews, a longevity study (Sathyan et al., 2018)

- **Cognitive ability (IQ)**
- 919 young males, 480k SNPs
- Greek schizophrenia study (Stefanis et al., 2004)

Nikos Stefanis, Alex Hatzimanolis, Nikolaos Smyrnis,
Dimitrios Avramopoulos, University of Athens

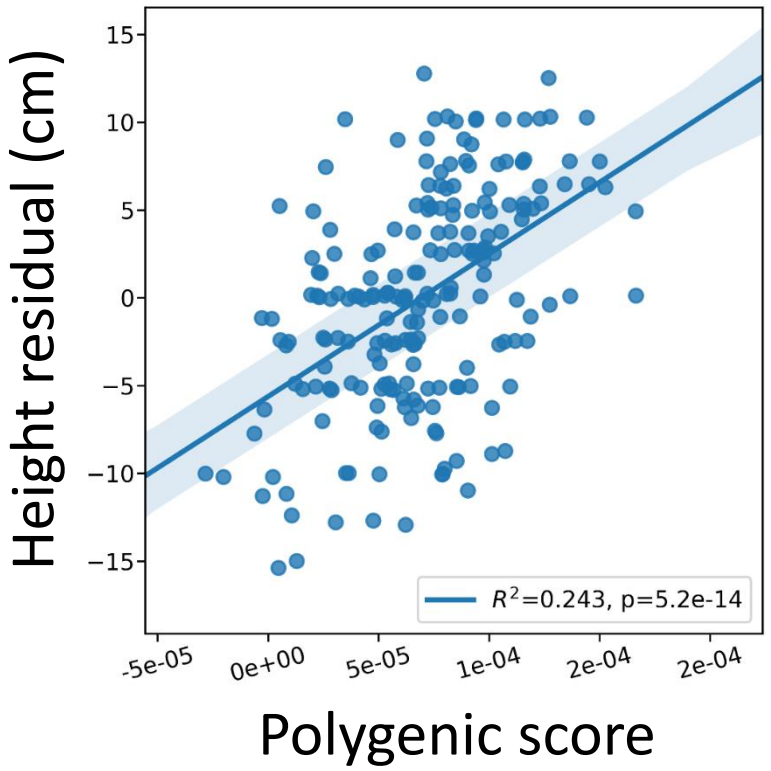
Polygenic scores

- **Height**
- Yengo et al., 2018
- 700k individuals

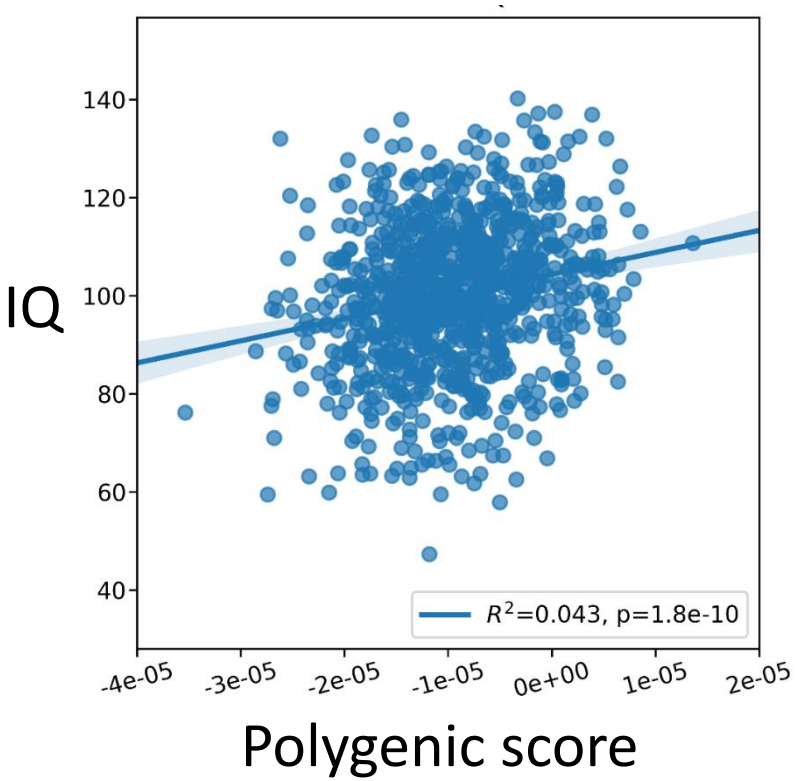
- **IQ**
- Savage et al., 2018
- 270k individuals

- Cross-validation for tuning parameters

Height, $r_{ps}^2 \approx 24\%$

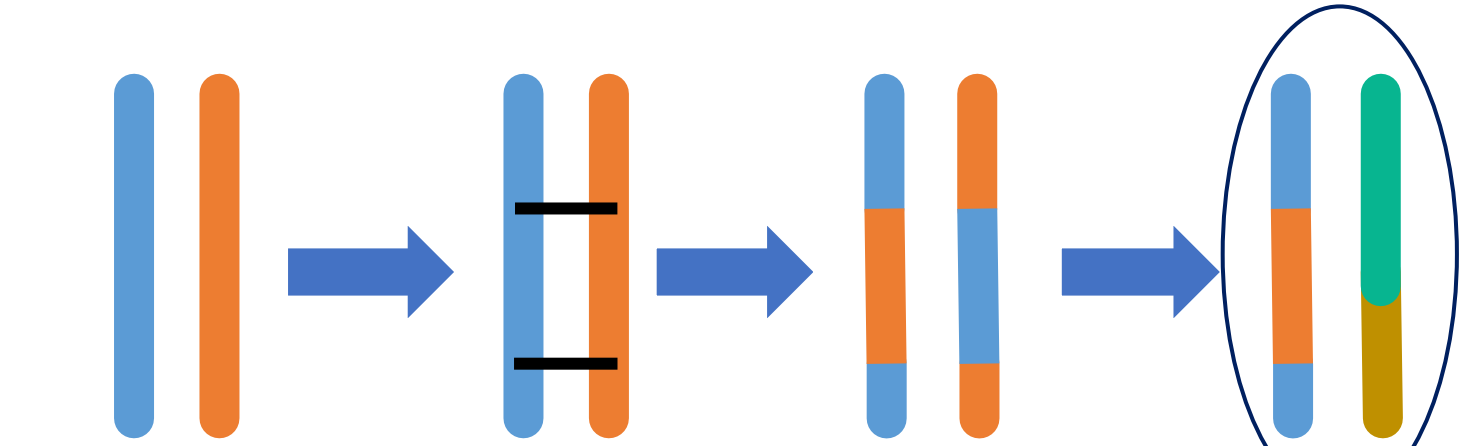


IQ, $r_{ps}^2 \approx 4.3\%$



Simulating embryos

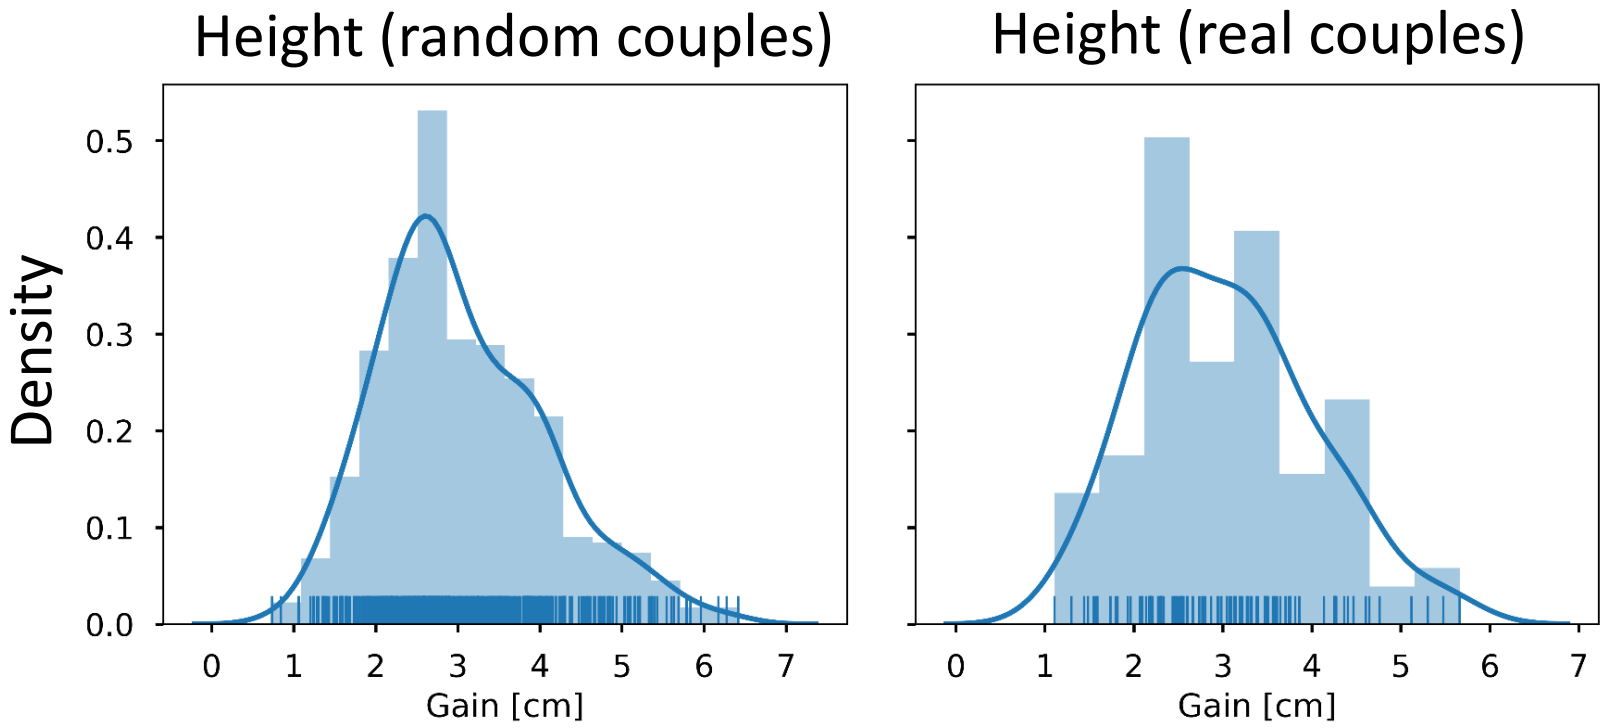
- To simulate a gamete:
  - Poisson number of crossovers, random placement
  - Independent random segregation
- Gametes paired to form diploids
- Polygenic scores computed and phenotypes predicted



Parental chrs

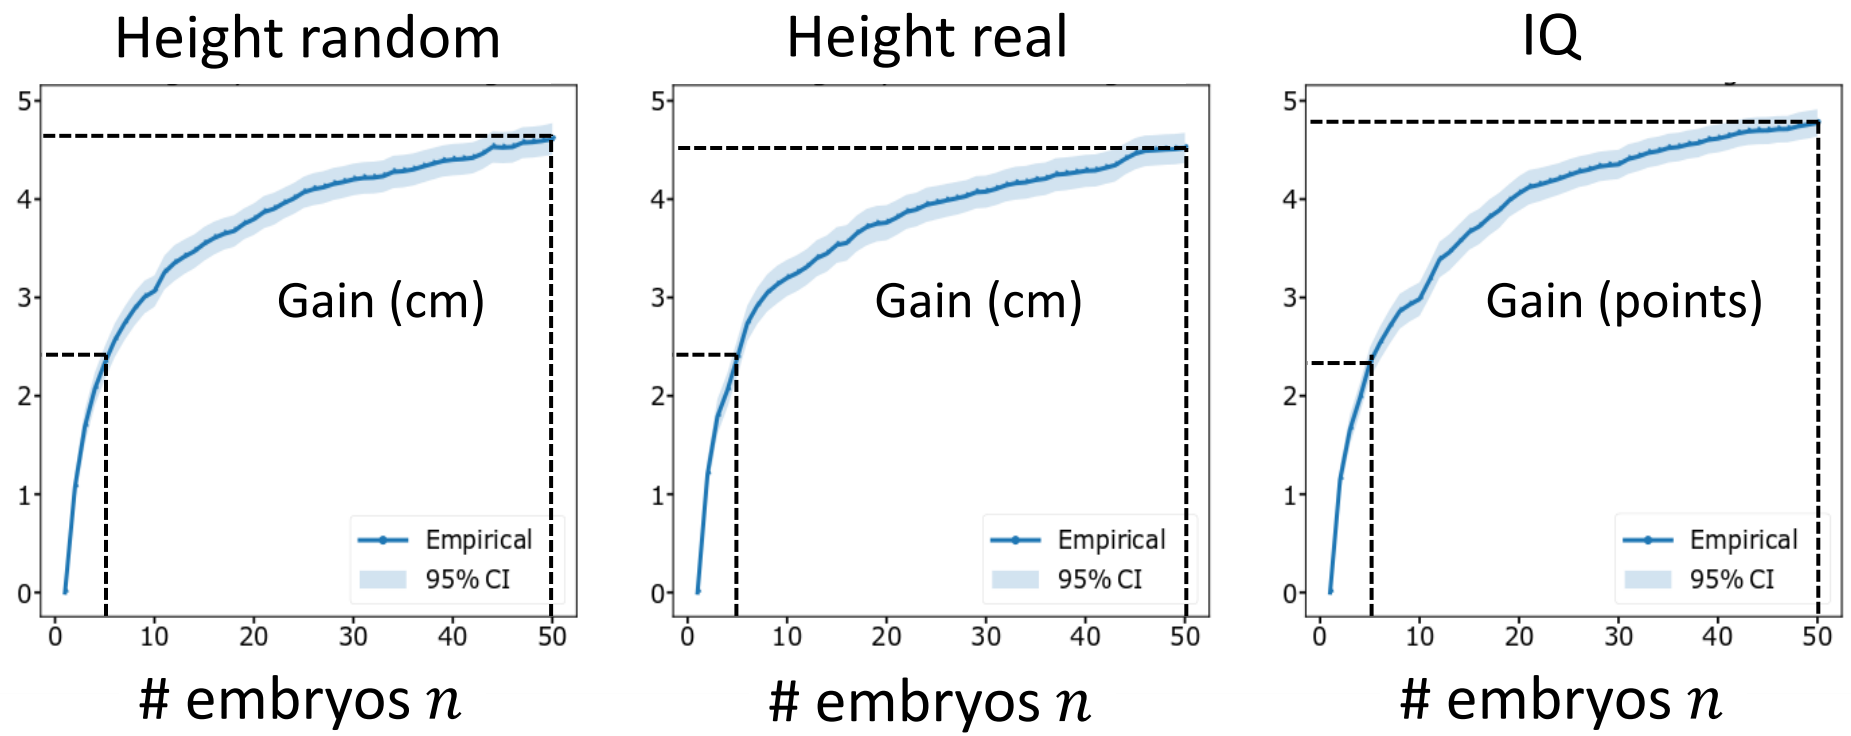
Experiments ($n = 10$ embryos)

- Gain in height: **2-4 cm**
- Real/random families behave similarly
- Gain in IQ: **2-4 points**



More/less embryos?

- $n = 50$: gain is ≈4.5 cm/IQ points
- $n = 5$: gain is ≈2.5 cm/IQ points



Questions

- Are these results expected?
- What happens for even more embryos?
- What happens if we have better predictors?

- We need a quantitative genetic model

A model for the polygenic scores of sibs

- $PS_1, PS_2, \ldots, PS_n \sim MVN(\mathbf{0}_n, \mathbf{\Sigma})$
- $\mathbf{\Sigma} = \sigma_z^2 r_{ps}^2 \begin{bmatrix} 1 & \cdots & 1/2 \\ \vdots & \ddots & \vdots \\ 1/2 & \cdots & 1 \end{bmatrix}$

$\boldsymbol{\sigma_z^2}$: variance of trait

$\boldsymbol{r_{ps}^2}$: proportion of variance explained by PS

For siblings: $\mathrm{Cov}(PS_i, PS_j) = \frac{1}{2}\mathrm{Var}(PS_i)$

The gain under the model

- The **gain**: (PS of best embryo) minus (average PS for the family)
- $G = \max(PS_1, PS_2, \dots, PS_n) - \frac{1}{n}(PS_1 + PS_2 + \cdots + PS_n)$
- $E(G) = E(\max(PS_1, PS_2, \dots, PS_n))$

Decomposing the polygenic scores

- $\boldsymbol{PS} \sim MVN(\mathbf{0}_n, \boldsymbol{\Sigma}) = \boldsymbol{Y} + \boldsymbol{Z}$
- $\boldsymbol{\Sigma} = \sigma_z^2 r_{ps}^2 \begin{bmatrix} 1 & \cdots & 1/2 \\ \vdots & \ddots & \vdots \\ 1/2 & \cdots & 1 \end{bmatrix} = \frac{1}{2}\sigma_z^2 r_{ps}^2 \begin{bmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{bmatrix} + \frac{1}{2}\sigma_z^2 r_{ps}^2 \begin{bmatrix} 1 & \cdots & 1 \\ \vdots & \ddots & \vdots \\ 1 & \cdots & 1 \end{bmatrix}$

$\boldsymbol{Y}$ — Independent normals

$\boldsymbol{Z}$ — Identical normals

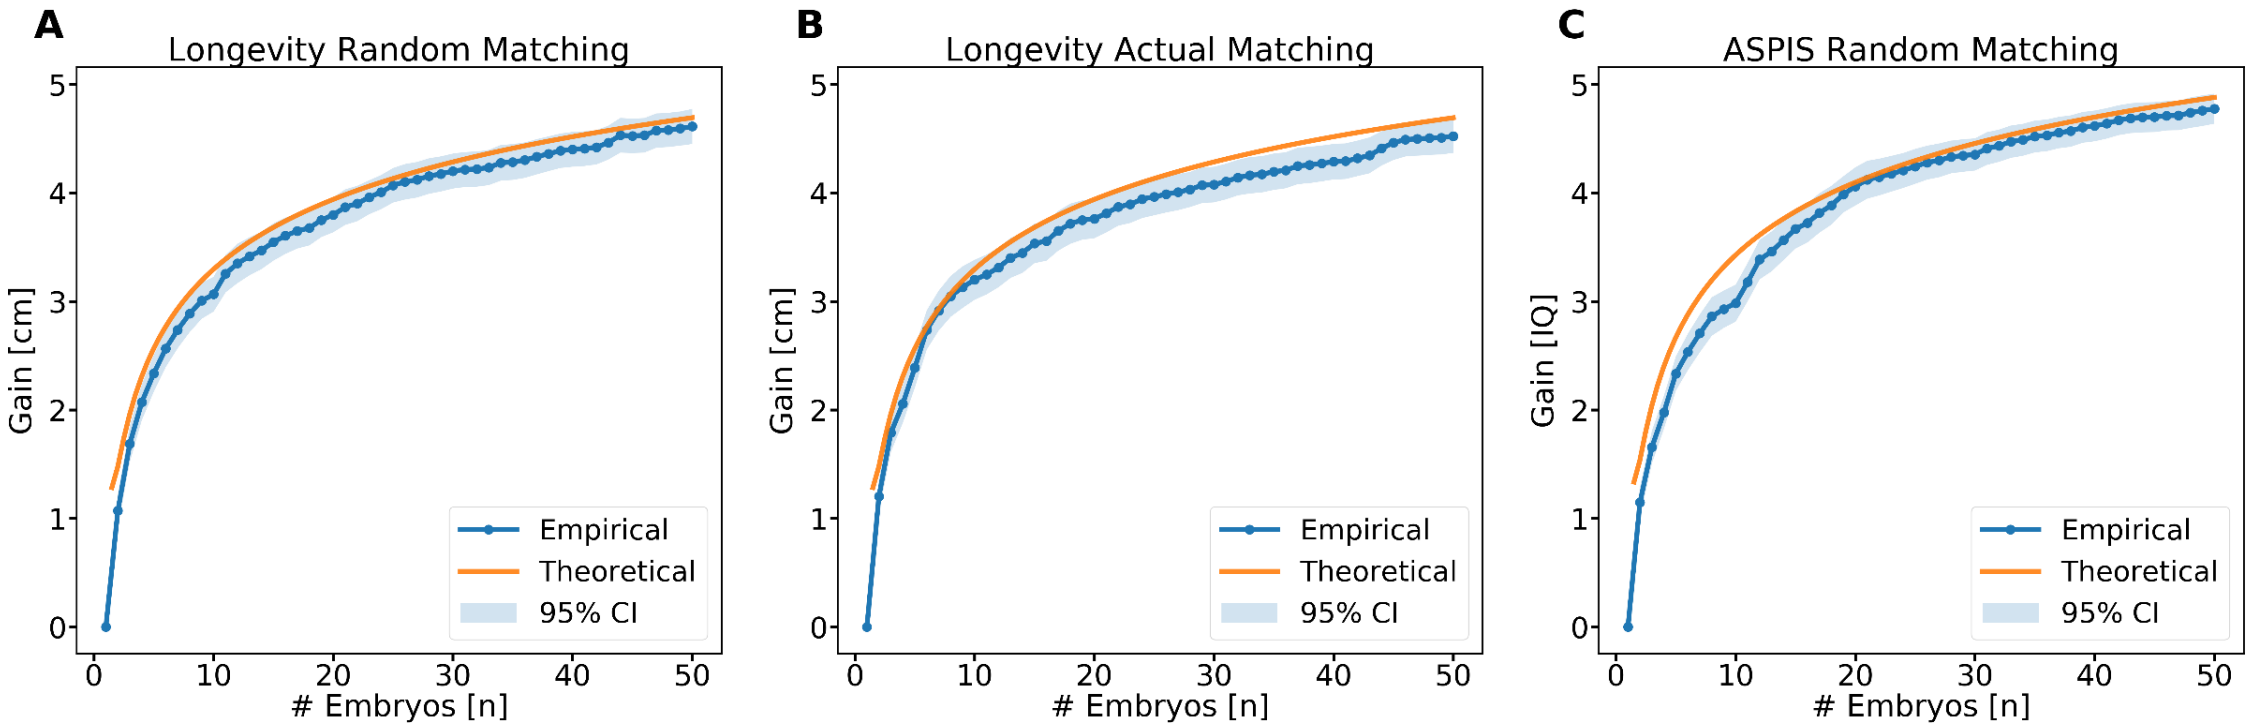
Do not affect the max

The mean gain

- $E(G) = E(\max(Y_1, Y_2, \dots, Y_n))$
- $Y_i \sim N\left(0, \frac{1}{2}\sigma_z^2 r_{ps}^2\right)$ are independent
- Using extreme value theory:
- $$E(G) = \frac{\sigma_z r_{ps}}{\sqrt{2}}\left[\Phi^{-1}\left(1-\frac{1}{n}\right) + \frac{\gamma}{n\phi\left(\Phi^{-1}\left(1-\frac{1}{n}\right)\right)}\right]$$

$\boldsymbol{\Phi^{-1}}$: inverse normal CDF
$\boldsymbol{\phi}$: normal PDF
$\boldsymbol{\gamma}$: Euler-Mascheroni constant

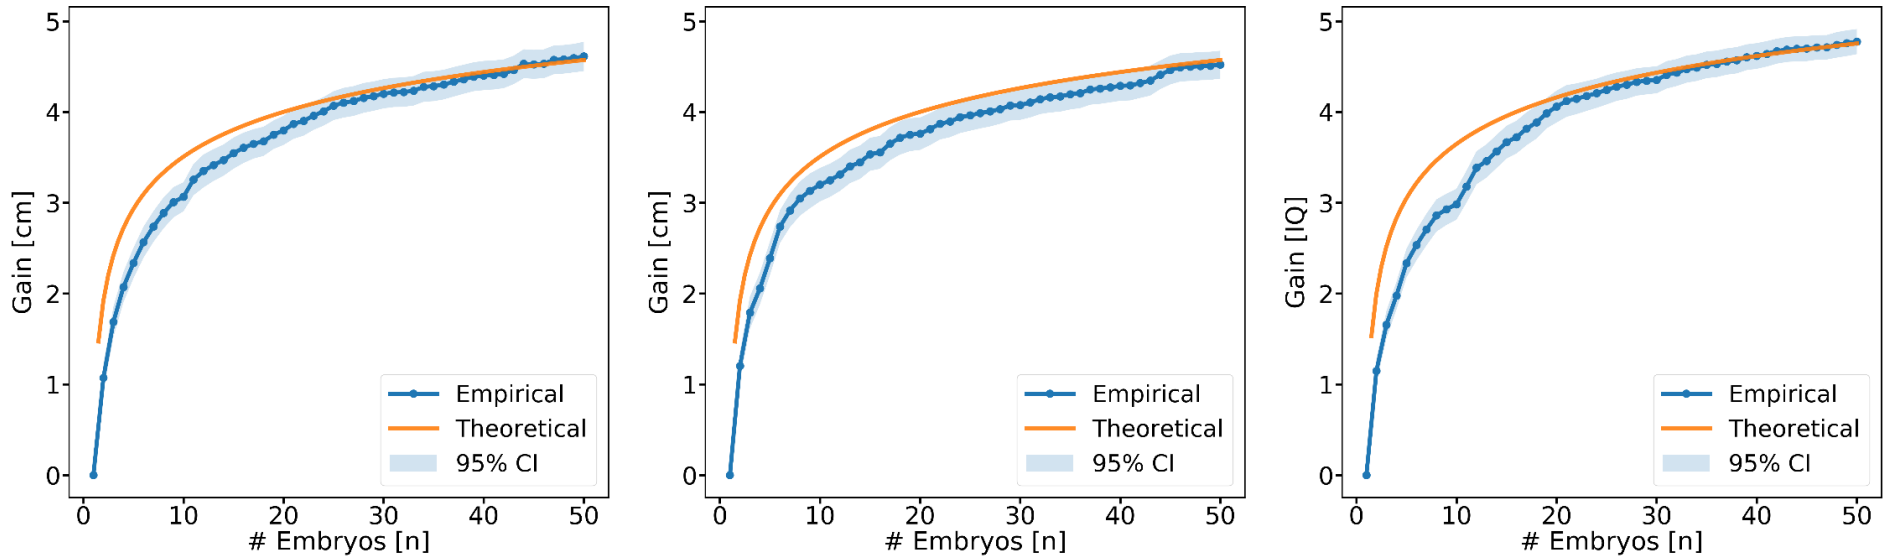
Confirming the theory



A useful approximation

σ_z: SD of the trait

$$E(Gain) \approx \underbrace{\sigma_z r_{ps}}_{\text{Accuracy of the score}} \cdot \underbrace{O\left(\sqrt{\log n}\right)}_{\text{Contribution of the number of embryos}}$$



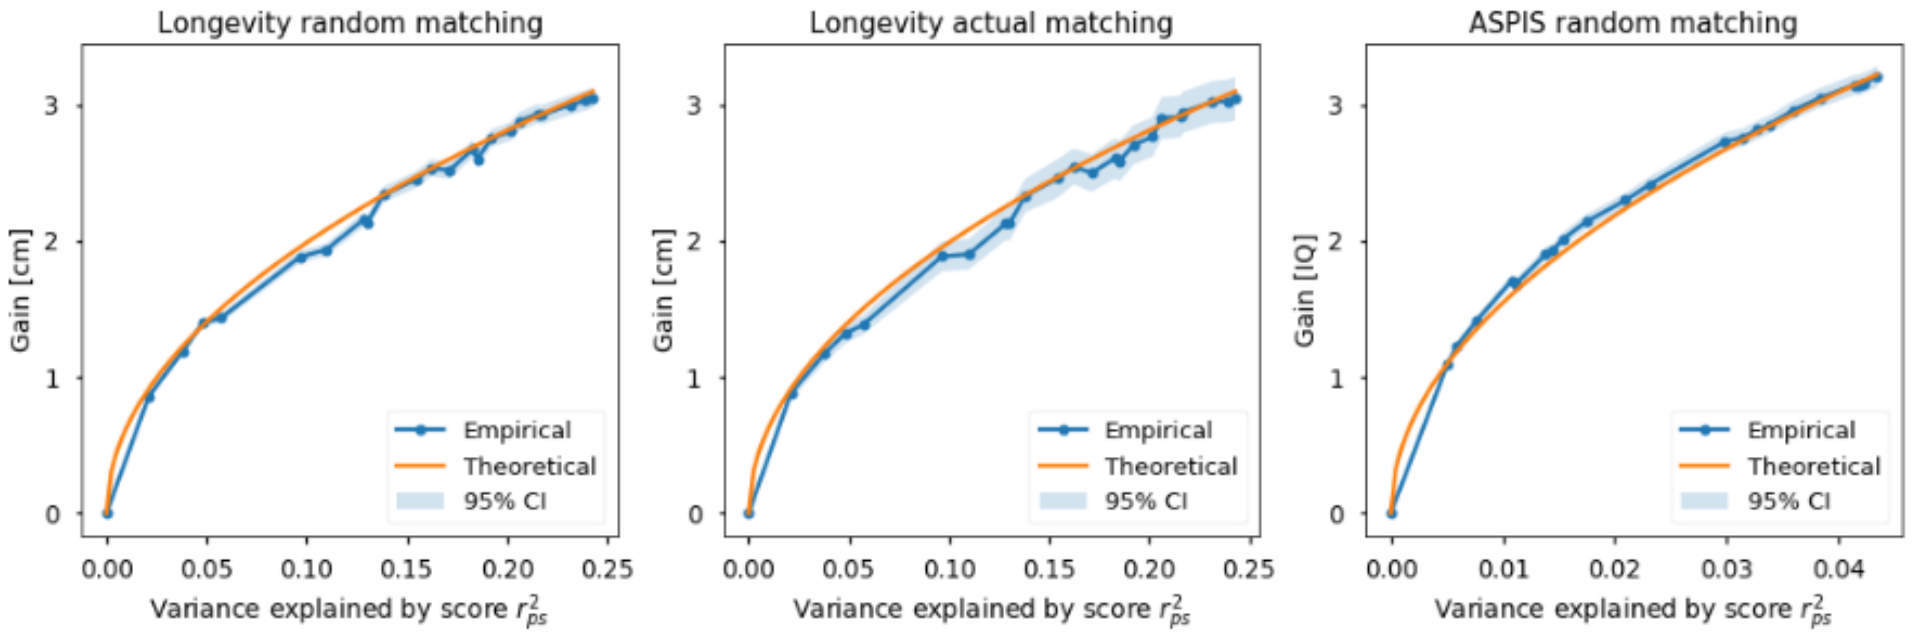
The effect of the predictor

- $E(G) \propto r_{ps} = \sqrt{r_{ps}^2}$

Can estimate the gain for future predictors!

Using growing subsets of chrs

$n = 10$ embryos

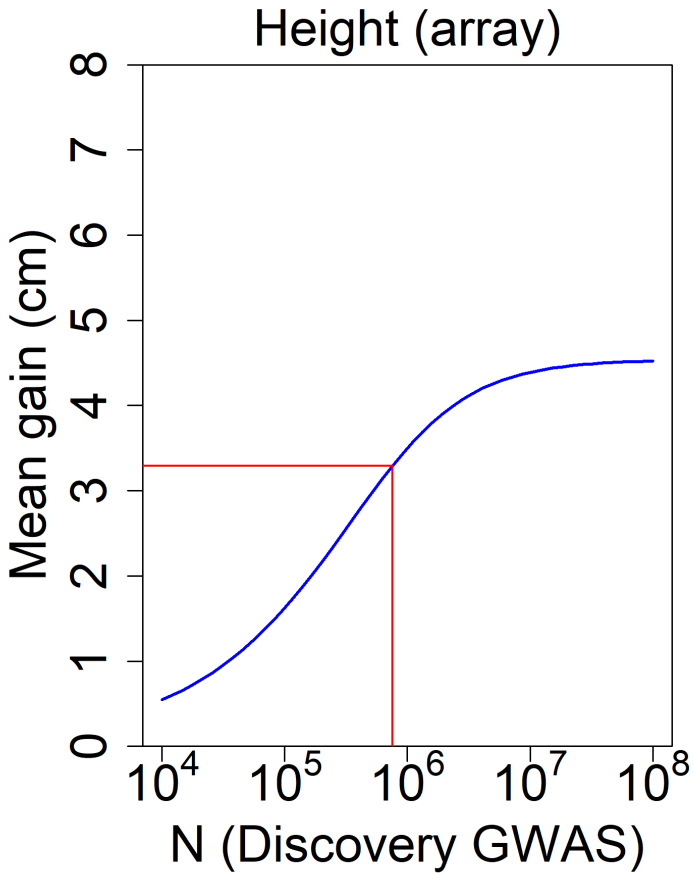


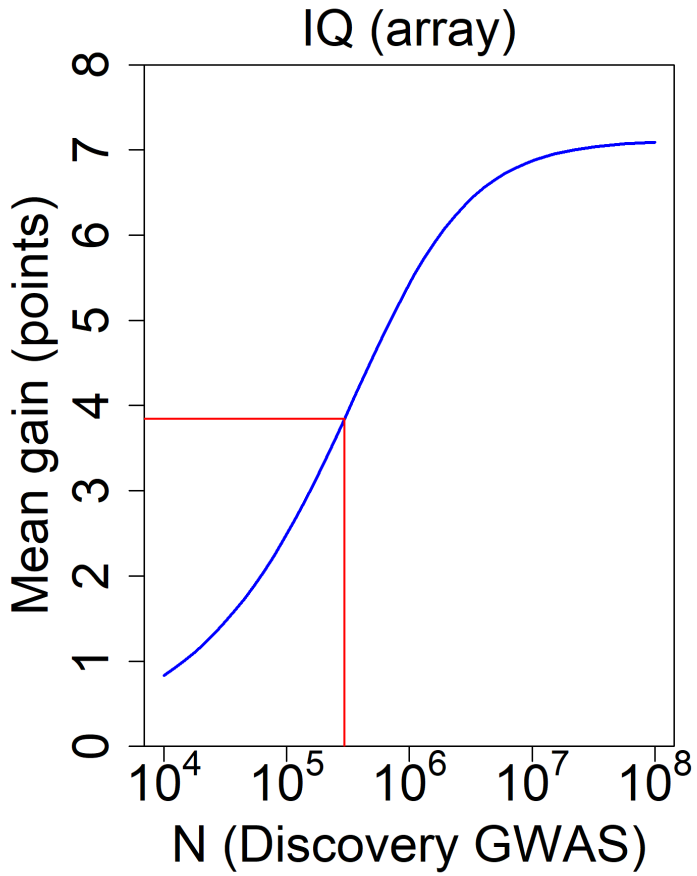
Larger GWASs?

- $r_{ps}^2 = \frac{h_{snp}^2}{1+\frac{M}{Nh_{snp}^2}}$

- M: Effective #markers
- N: GWAS sample size
- h_{snp}^2: chip-based heritability

- Wray et al., 2019
- Pasaniuc and Price, 2017





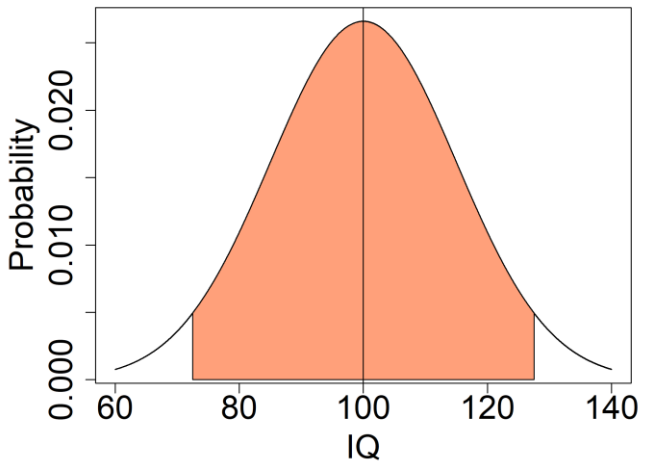
10 embryos

The actual gain is uncertain

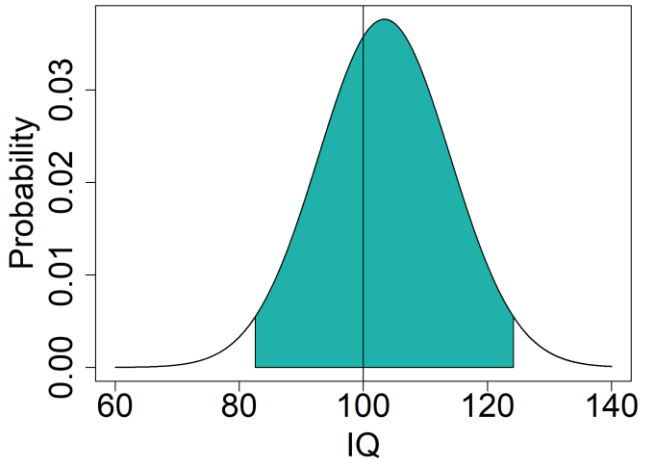
1. Embryos are random
2. Non-score genetic factors
3. Non-genetic factors

$n = 10, h^2 = 0.5, r_{ps}^2 = 4.3\%$

No selection
[72,128]

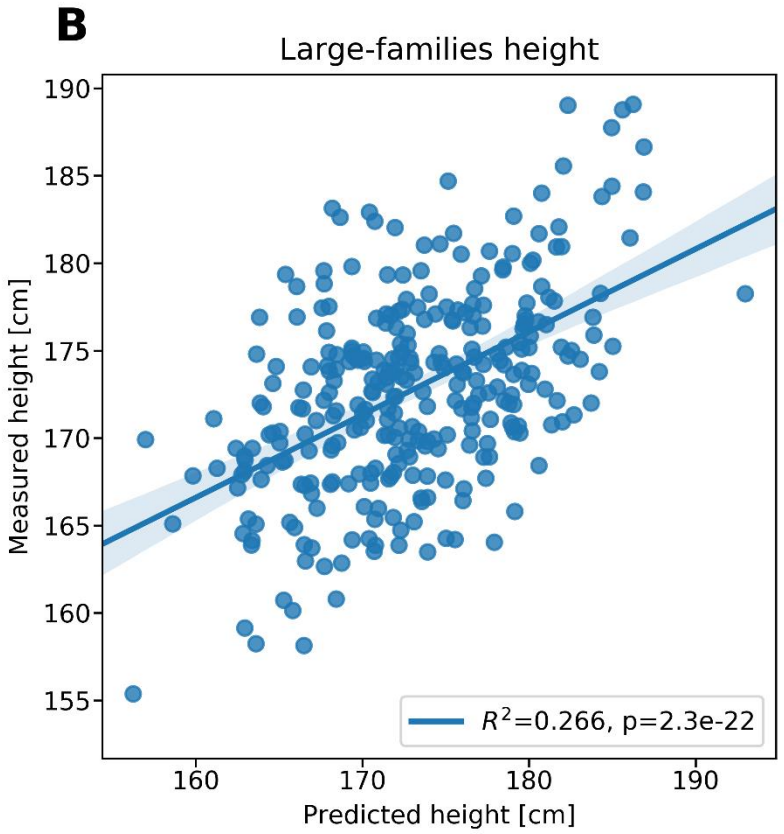


Selection
[83,124]



But what about an actual experiment?...

- Ethical issues + too long
- But we can consider large nuclear families
- 28 Ultra-orthodox Jewish families (Israel/US)
- 9.6 **adult** children per family (range: 3-20)
- Genotype + height available!
- Danny Zeevi, Leonid Kruglyak, UCLA

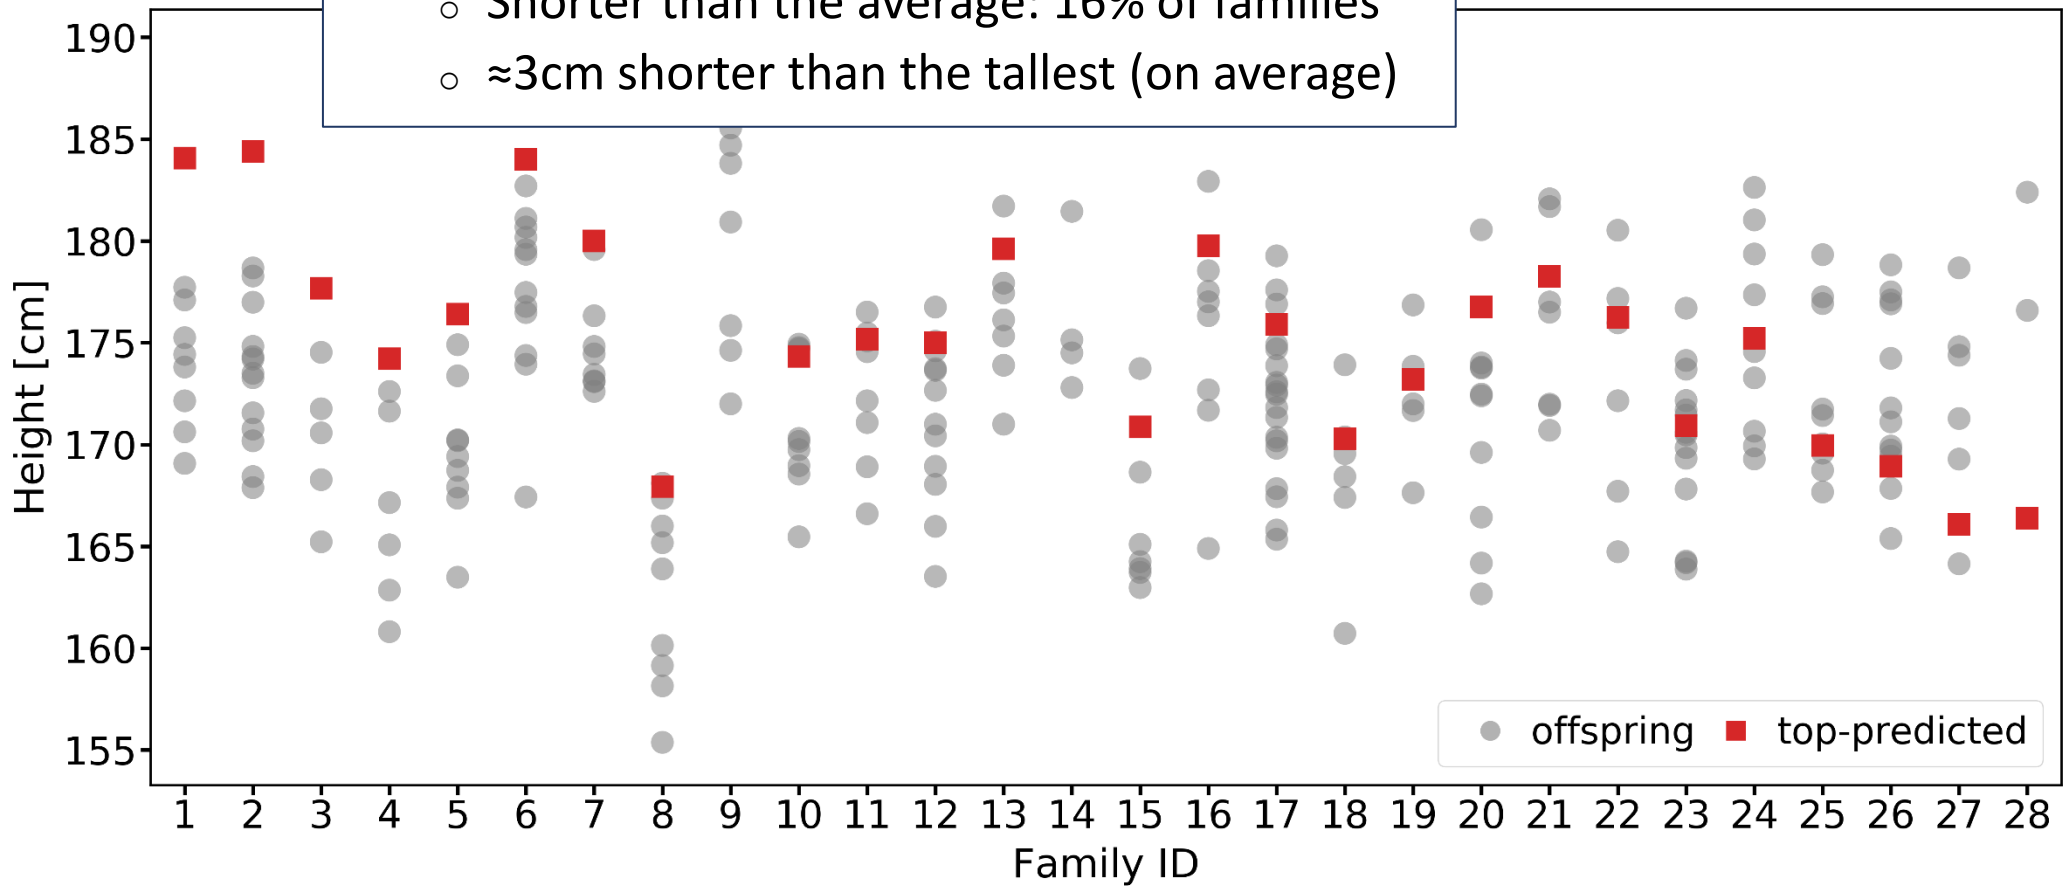


An “experiment”

Top-scoring embryo ($n = 7$) is:

- Tallest: 32% of families
- Shorter than the average: 16% of families
- ≈3cm shorter than the tallest (on average)

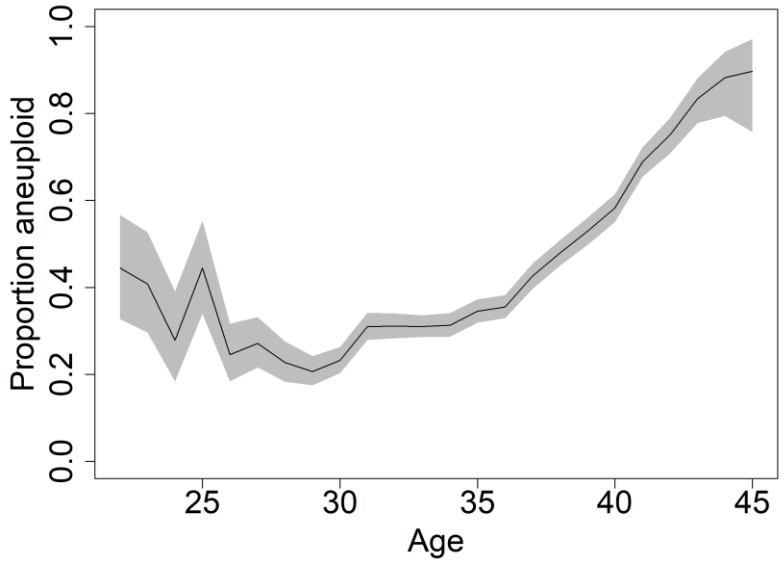
Danny Zeevi, Leonid Kruglyak, UCLA



Many practical limitations

- Prediction accuracy lower within families and across populations, assortative mating
- Advanced maternal age: less viable embryos
- Selection for multiple traits
  - Gain decreases by $\sqrt{T}$-fold
- Risk of unknown health issues

From Franasiak et al., 2014



Summary

- Current gain: ≈2-3 cm/IQ points
- Improved predictors will increase the gain substantially ($\propto r_{ps}$, but only up to the heritability)
- More embryos will not ($\propto \sqrt{\log n}$)
- Actual gain uncertain and practically limited
